Free-floating right atrium thrombus associated with acute pulmonary thromboembolism

Abstract: Mobile right heart thrombus represents a rare situation that complicates acute pulmonary thromboembolism and is associated with high rates of mortality. In such cases, anticoagulation with heparin, thrombolysis, surgical embolectomy or percutaneous catheter intervention represent possible therapeutic measures, but no certain guideline recommendations have been proposed for this particular setting and the treatment should be conducted by guiding after local possibilities and experience.

We present the case of a 69-year old male patient, with stable vital signs, that was admitted for acute pulmonary thromboembolism. Transthoracic echocardiography revealed right heart dilatation, acute pulmonary artery hypertension (PAH) and a serpiginous mobile thrombus located in the right atrium prolapsing into the right ventricle (RV) with maximum length 54 mm. After 24 hours of thrombolysis with streptokinase, the patient evolution was favorable, with disappearance of thrombus, RV function improvement and reduction of PAH. No post-thrombolysis complications were observed and the patient was discharged with indication of oral anticoagulation for long term.

Keywords: right atrium thrombus, pulmonary thromboembolism, thrombolysis

CASE PRESENTATION
We present the case of a 69-year old male patient, obese, dyslipidemic, former smoker (30 pack-years) who was admitted for shortness of breath and orthopnoea started two days before. His past medical history consisted of deep vein thrombosis in the left lower limb for approximately two months that was therapeutically neglected.

Clinical examination revealed: sinus tachycardia 110 bpm, blood pressure 110/70 mmHg, respiratory rate 32/minute, oxygen saturation 88% at room air, no fever, and painful and swollen left lower limb.

Electrocardiogram at rest showed sinus rhythm 110 bpm, right bundle branch block, S1Q3T3 pattern and negative T waves in leads V1-V4.

Laboratory exams: high-positive D-dimer; presence of inflammatory syndrome (leucocytes 14500/mm³, fibrinogen 641 mg/dl, CRP 61.4 mg/l); moderate elevated myocardial enzymes (cardiac troponine I 1.03 ng/ml, CK-MB 28 U/L, LDH 522 U/L, AST 68 U/L); hypercholesterolemia (total cholesterol 226 mg/dl, LDL cholesterol 151 mg/dl); normal renal function, electrolytes and fasting glucose.

Transthoracic echocardiography revealed acute right heart dilatation, medium right ventricle (RV) diastolic diameter 49 mm, RV lateral wall 4 mm, with RV compressing the left ventricle (LV), interventricular septum (IVS) with paradoxical movement, RV free wall hypokinesia, tricuspid annular plane systolic excursion (TAPSE) 15 mm, RV systolic pressure 39 mmHg (estimated systolic pulmonary arterial pressure – 60 mmHg) – all indirect aspects of high probability of pulmonary embolism (PE). Moreover, we could visualize serpiginous mobile thrombus located in the RA prolapsing in the RV with maximum length 54 mm (Figures 1, 2).

Taking into consideration the high probability of PE and according to the latest guidelines¹, Pulmonary Embolism Severity Index (PESI) of 139 points included the patient into the very high risk class.

Considering the RV overload, the cardiovascular surgeon contraindicated a surgical approach of the thrombus.

Thus, based on surgeon opinion, clinical examination, laboratory exams, electrocardiographic and echocardiographic aspects, we decided to perform systemic
thrombolysis to the patient. We have chosen streptokinase with the following regime: 250,000 UI in bolus for 30 minutes, followed by 100,000 UI/hour for 36 hours. Afterwards, unfractionated heparin was continued until proper oral anticoagulation was obtained.

Echocardiography reevaluation after 24-hour post-thrombolysis showed the absence of intracavitary thrombus with RV function improvement, normal kinetic of IVS, RV systolic pressure reduced to 23 mmHg (estimated systolic pulmonary arterial pressure – 35 mmHg), TAPSE 20 mm (Figures 3, 4). Pulmonary artery computer tomography revealed normal main pulmonary arteries with distal thrombus in the left pulmonary artery and non-occlusive thrombi in subsegmentary branches (Figure 5).

The patient evolution was favorable during hospitalization, without hemodynamic impairment or post-thrombolysis complications. After seven days, the patient was discharged with indication of oral anticoagulation for long term.
In our case, the thrombolytic treatment was the first line option and no thrombi were observed after 24 hours of treatment. Thrombolysis represents a simple and effective method with various advantages including fast reduction of the pulmonary artery pressure and improvement of RV function by dissolving the intracardiac or pulmonary thrombi. However, especially in patients with mobile right heart thrombi, the risk of clot detachment and further embolization to the lungs which are already affected is even higher. Another study that evaluated the thrombolytic treatment in PE showed that out of 12 patients with right heart thrombi, three died before the onset of treatment, seven had a good evolution while two subjects had to perform adjunctive surgery because the persistence of massive thrombus. Thus, surgical embolectomy represents another treatment option and is indicated especially in hemodynamically unstable patients where thrombolysis is contraindicated or ineffective. However, more evidence suggest that this procedure is associated with low mortality when early performed and may be extended to hemodynamically stable patients with RV dysfunction.

Pulmonary hypertension (PH) is another positive element for PE, with good prognosis both for the diagnosis and chronic thromboembolic pulmonary hypertension. In our case, the acute PH was moderate (55 – 60 mmHg) and after thrombolysis the value reduced to 35 mmHg. This may be explained by the rapid and efficient onset of thrombolytic treatment which has been proven to better reduce the acute PH compared to patients that did not receive thrombolysis. Moreover, the presence of RA thrombus might be another contributor to the increased PH at presentation.

CONCLUSIONS

Acute pulmonary thromboembolism represents one of the major cardiovascular emergencies by having a vital risk especially if it is associated with mobile right heart thrombus. Heparin anticoagulation, percutaneous catheter intervention, thrombolysis or surgical embolectomy are the treatment of choice, with better results for the last two options. No certain guideline recommendations are made for this particular situation and the treatment should be conducted by guiding after local possibilities and experience. Further studies should be performed in order to establish which method is more efficient and with lower risk.
